## Experimental section

### S1. Material synthesis

The following chemicals are used as received without further purification: Potassium permanganate (Sigma-Aldrich, ACS reagent,  $\geq 99.0\%$ ); Manganese (II) nitrate tetrahydrate (Fisher chemical, AR  $\geq 98.0\%$ ); Nickel (II) nitrate hexahydrate (Sigma-Aldrich, ACS reagent,  $\geq 99.0\%$ ); Ammonium chloride (Sigma-Aldrich, ACS reagent,  $\geq 95\%$ ); Zinc trifluoromethanesulfonate (Sigma-Aldrich, ACS reagent, 98%); Manganese bis(trifluoromethanesulfonate) (Sigma-Aldrich, ACS reagent,  $\geq 98\%$ ); Poly(vinylidene fluoride) (Sigma-Aldrich, average Mw  $\sim 534,000$  by GPC, powder) N-methyl-2-pyrrolidone (Sigma-Aldrich, ACS reagent,  $\geq 99.0\%$ ).

Cation-defective  $\text{NiMn}_3\text{O}_7$  cathode material  $\text{V}_m\text{-NMO}$  was synthesised according to the previous literature.<sup>1</sup>  $\text{KMnO}_4$  aqueous solution (0.04 M, 18 mL),  $\text{NH}_4\text{Cl}$  aqueous solution (0.04 M, 18 mL) and  $\text{Ni}(\text{NO}_3)_2$  aqueous solution (1 M, 4 mL) were added stage by stage and vigorously stirred for 25 min. Then the acquired mixture was shifted in an autoclave and heated in an electric oven at 200 °C for 24 h. The resulting precursor was gathered and washed (deionised water three times and ethanol one time), then dried in an oven at 60 °C overnight. NMO was synthesised following the same process without the addition of  $\text{NH}_4\text{Cl}$  aqueous solution.  $\text{V}_n\text{-NMO}$ ,  $\text{V}_o\text{-NMO}$  and  $\text{V}_p\text{-NMO}$  were synthesised following the same heating process by adjusting the addition of  $\text{NH}_4\text{Cl}$  aqueous solution to 0.08 M (18 mL), 0.4 M (18 mL) and 1 M (18 mL).

### S2. Material characterisation

X-ray diffraction (XRD) patterns were obtained by a STOE SEIFERT diffractometer with detected angular range of  $2^\circ < 2\theta < 40^\circ$  with a Mo X-ray radiation source. The morphology and chemical states of the as-prepared materials were evaluated by scanning electron microscope (SEM, Jeol 7600F SEM), transmission electron microscopy (TEM JEOL, JEM-2100 and ARM200F) and X-ray photoelectron spectroscopy (XPS, Thermo Scientific K-alpha photoelectron spectrometer) analysis, respectively. Data processing of XPS results was conducted using CasaXPS software with the calibration of adventitious carbon binding energy at 284.8 eV. Raman and FT-IR data were obtained on a Raman Spectroscopy (Renishaw Raman microscope spectrometer with a laser wavelength of 514.5 nm) and Attenuated Total Reflectance Fourier transform infrared spectroscopy (ATR-FTIR, BRUKER, platinum-ATR). The mass change during annealing was recorded by a Thermogravimetric analyser (TGA) (PerkinElmer TGA 4000 System). The mass of the active materials was weighed accurately by an analytical balance (Ohaus;  $\delta = 0.01$  mg). Crystallographic structures were stimulated via VESTA software by applying standard ICSD CIF documents. The Mn, Ni and Zn K-edges X-ray Absorption Spectra of electrode plates were collected at B18@Diamond Light Source. The monochromatic beam between 6.35 keV and 10.55 keV ( $k_{\text{max}} = 16$ ) was introduced through a bending magnet and Pt-coated Si(111) double crystal monochromator. The beam size at the sample was approx.  $1.0 \times 1.0 \text{ mm}^2$  (V x H) and the photon flux was  $\sim 10^{11}$  ph/s (no attenuation). The XAFS spectra were collected in transmission mode, and the intensity of the incident beam (I0) and the transmitted beam (It) was monitored by ionisation chambers (filled with a mixture of He and N2). The sample was made of electrode carbon paper (D:8mm) and was cut into four pieces, stacked together, sealed with Kapton tape, and mounted on the sample rack. The XAFS measurements were performed under R.T. The XAFS of each sample was measured two times and merged to improve the signal-noise ratio. Mn, Ni, and Zn foil were measured simultaneously for each sample as a reference for energy calibration. The NEXAFS experiment was performed at the B07-B beamline of Diamond Light Source (UK).<sup>1</sup> NEXAFS measurements of O K-edge, Mn L-edge, and Ni L-edge were performed in total electron yield (TEY) mode in the ES-2 end station for Ambient Pressure NEXAFS.<sup>2</sup> The pristine, charged, and discharged electrode, as well as  $\text{Mn}_2\text{O}_3$  and  $\text{MnO}_2$  powder reference, were dispersed on carbon tape by pressing, which ensured good conductivity. The samples were illuminated by an incident beam sourced from a bending magnet and plane grating monochromator (PGM) with a spot size of approx.  $200 \mu\text{m} \times 200 \mu\text{m}$ . The pressure in the specimen chamber is controlled at  $1 \times 10^{-7}$  mbar. Three repetitions of NEXAFS spectrum were collected and merged to improve the signal-to-noise ratio for every edge. The energy resolution was set to 0.1 eV for each repetition. The energy shifts of O K-edge, Mn L-edge, and Ni L-edge were calibrated by the spectra of standard  $\text{Mn}_2\text{O}_3$  and NiO, respectively. The NEXAFS spectra were divided by the incident beam intensity. X-ray Absorption Spectroscopy data processing and analysis using Demeter.

### S3. Electrochemical measurements

The electrochemical performance of  $\text{NiMn}_3\text{O}_7$  was tested by assembling them into coin cells. Typically, 70 wt% of

as-prepared was mixed with 20 wt% of Carbon black Super-P and 10 wt% of poly(vinylidene fluoride) (PVDF) in N-methylpyrrolidone (NMP) solvent. The resulting slurry was then deposited onto carbon paper and vacuum dried for 8 h under 80 °C to form the cathode part, which was matched with 500 um thickness zinc plate anode to completely form a coin cell configuration using 3 M Zn(OTf)<sub>2</sub>, 0.2 M Mn(OTf)<sub>2</sub> electrolyte and Whatman GF/A glass fibre as the separator.<sup>3</sup> With a diameter of 1.4 cm, the loading mass of cut discs of electrodes is between 1.0 and 2.5 mg cm<sup>-1</sup>. All battery performances were characterised on the Neware battery system, and the cyclic voltammetry curves profiles were performed within 0.9–1.9 V (vs. Zn<sup>2+</sup>/Zn). Cyclic voltammetry and EIS testing were performed with VMP3 Biotech potentiostat.

#### Note 1: Estimation of the capacitive and diffusion-controlled contributions

To distinguish quantitatively the capacitive and diffusion-controlled contributions to the current, cyclic voltammetry curves were recorded at different sweep rates. In general, there is a relationship between the measured peak current (*i*) and sweep rate (*v*) in a CV scan, which follows the power law:

$$i = av^b$$

$$\text{alternatively, } \log(i) = \log(a) + b \times \log(v)$$

The b-value can therefore be obtained by fitting the log(*i*) versus log(*v*) slope. A b value of 0.5 suggests a diffusion-controlled behaviour, while a b value of 1.0 indicates a capacitive behaviour. The capacitive contribution and the diffusion-controlled contribution can be further distinguished. By quantitatively assuming that the current (*i*) is a combination of the capacitive and the diffusion-controlled processes:

$$i = k_1 v + k_2 v^{\frac{1}{2}}$$

*k*<sub>1</sub> can be used to estimate capacitive and diffusion-controlled contributions.

#### Note 2: Study on Galvanostatic Intermittent Titration Technique (GITT)

GITT was employed to establish the thermodynamic voltage-composition relationship, which is consistent with the equilibrium phase diagram.<sup>4,5</sup> The diffusion coefficients of Zn<sup>2+</sup> ions were evaluated from the GITT data. In the GITT process, the transient voltage induced by the application of a current pulse is studied as a function of time. The GITT testing undergoes charge/discharge for 15 cycles under 0.1 A g<sup>-1</sup> to reach a stable state. Subsequently, a galvanostatic pulse of 30 mA g<sup>-1</sup> was applied to the assembled coin cell for 20 minutes duration, after which following with a 2 hours relaxation open circuit step for the equilibrium phase (defined as < 2 mV h<sup>-1</sup>). These steps repeated until the batteries reached fully charged/discharged states.

The diffusion coefficients of the charge carriers follow the equation:

$$D_{\text{charge carriers}} = \frac{4}{\pi} \left( \frac{n_M V_M}{S} \right)^2 \left[ \frac{\Delta E_s}{\tau \left( \frac{dE_\tau}{d\sqrt{\tau}} \right)} \right]^2 \left( \tau \ll L^2 / D_{\text{charge carriers}} \right)$$

Where  $\tau$  stands for the dwell time of the constant current pulse (set as 20 min in this research); *S* corresponds to the interface area of cathode material and electrolyte (unit: cm<sup>2</sup>, refers to the geometric area of the electrode); *n<sub>M</sub>* and *V<sub>M</sub>* are the moles (unit: mol) of NiMn<sub>3</sub>O<sub>7</sub> and molar volume (unit: cm<sup>3</sup> mol<sup>-1</sup>), respectively;  $\Delta E_s$  and  $\Delta E_\tau$  are the shift in steady-state voltage and the total cell voltage after applying a current pulse in a single-step GITT testing, eliminating the *i<sub>R</sub>* drop, respectively. *L* refers to the cathode thickness. With the condition that the variation of the

cell voltage ( $\Delta E_c$ ) is found to have a linear relationship with  $\tau^{1/2}$ , the above equation can be simplified into the following equation:

$$D_{charge\ carriers} = \frac{4}{\pi\tau} \left( \frac{n_M V_M}{S} \right)^2 \left[ \frac{\Delta E_s}{\Delta E_\tau} \right]^2$$

#### S4. Computational details

All the density functional theory (DFT) calculations were performed using the Vienna Ab-initio Simulation package (VASP)<sup>6, 7</sup>. We used the projector augmented wave (PAW) method, with the plane-wave cut-off of 420 eV for the expansion of the wave functions, which provided bulk total energies converged to within 10<sup>-5</sup> eV<sup>8</sup>. For the structural optimisation, we chose a convergence criterion of 0.01 eV/Å, and we used the Perdew-Burke-Ernzerhof (PBE) generalised gradient approximation (GGA) as the exchange-correlation functional<sup>9, 10</sup>. A gamma-centred 4x4x1 Monkhorst-Pack (MP) grid was used. The ideal NiMn<sub>2</sub>O<sub>3</sub>(100) models with three NiMn<sub>3</sub>O<sub>7</sub> layers with water molecules in between them were modelled from the optimised unit cells with lattice parameters of a=7.552 Å (Exp.: 7.514 Å), b=6.540 Å (Exp.: 6.507 Å) and c=20.623 Å (Exp.: 20.520 Å). As shown in Figure 4 (a), the two top NiMn<sub>3</sub>O<sub>7</sub> layers along with the water molecules in between them were relaxed and the bottom layers were fixed to mimic the bulk of the structure. A vacuum of ~15 Å was inserted along the surface's normal direction, which is sufficient to eliminate spurious interaction with the neighbouring image slabs. The dipole moment due to the presence of species was accounted for by using the methods of Neugebauer et al.<sup>11, 12</sup>. In this study, we also employed Grimme's dispersion correction (DFT+D3), as dispersion force might be significant for this system<sup>13</sup>. In previous studies, it has been reported that the localisation of electrons in *d*-orbitals of Mn<sup>4+</sup> and Ni<sup>2+</sup> ions is correctly represented by the Hubbard parameter ( $U_{eff}$ ) of 4.0 eV and 5.3 eV, respectively<sup>14</sup>. Therefore, in this study, we have used  $U_{eff}$  of 4.0 eV, 5.3 eV and 0 eV, respectively, for the *d*-orbitals of Mn<sup>4+</sup> and Ni<sup>2+</sup> ions and *p*-orbital for O<sup>2-</sup> ions. The adsorption energies ( $E_{ad}$ ) of the proton on the NiMn<sub>2</sub>O<sub>3</sub>(100) surface were evaluated using equation (1).

$$E_{ad} = E_{H/NMO} - E_{NMO} - E_H \quad (1)$$

where  $E_{H/NMO}$  is the total energy of the proton adsorbed on the NiMn<sub>2</sub>O<sub>3</sub>(100) surface,  $E_{NMO}$  is the total energy of the relaxed pristine NiMn<sub>2</sub>O<sub>3</sub>(100) surface and  $E_H$  is the total energy of a hydrogen atom in the gas phase. To obtain  $E_{H/NMO}$ , the adsorption of the H-atom was allowed on various sites on the NiMn<sub>2</sub>O<sub>3</sub>(100) surface with and without Mn<sup>4+</sup> defects, which includes a water molecule present between the NiMn<sub>2</sub>O<sub>3</sub> layers in an O-atom of the NiMn<sub>2</sub>O<sub>3</sub> layer and on the Mn<sup>4+</sup> ions. The atomic charges were calculated using the Bader charge analysis as implemented by Henkelman and co-workers<sup>15</sup>. The VESTA package was used for visualisation of the optimised structures and to measure the interatomic distances, bond angles and dihedral angles<sup>16, 17</sup>.
